**Abstract**

**Background:** Iatrogenic paresthesia in the third division of the trigeminal nerve remains a complex clinical problem with major medicolegal implications. However, most lawsuits can be prevented through better planning of procedures and by obtaining informed consent. The purpose of this article is to present the authors' clinical experience over the past 12 years, to review the principles of prevention and management of trigeminal paresthesia and to highlight the resulting medicolegal implications.

**Methods:** The files of all 165 patients referred to the oral and maxillofacial surgery department for evaluation of iatrogenic paresthesia in the third division of the trigeminal nerve were reviewed. The characteristics of the subgroup of patients who had taken an attending dentist to court were compared with those of the other patients.

**Results:** Surgical extraction of impacted molars was the main cause of paresthesia in 109 (66%) of the 165 subjects. The alveolar nerve was affected in 89 (54%) subjects, the lingual nerve in 67 (41%) subjects, and both nerves were affected in 9 (5%) subjects. There were more female than male patients (ratio 2.2:1). Lawsuits were initiated in 33 (20%) of the cases; patients who initiated lawsuits were younger, were more likely to have experienced anesthesia and were more likely to need microsurgery \((p < 0.001)\). Poor surgical planning and lack of informed consent were the most common errors on the part of the dentists.

**Conclusions:** An accurate evaluation of surgical indications and risk, good surgical technique, preoperative informed consent and sufficient postoperative follow-up should help to reduce the frequency of neurosensory deficits after dental treatment and attendant lawsuits.

**MeSH key words:** molar, third/surgery; postoperative complications; sensation; trigeminal nerve/injuries
results are often disappointing. The presence of anesthesia, dysesthesia or spontaneous pain also indicates poor prospects for recovery without surgical intervention. Overall, 25% of patients with iatrogenic paresthesia suffer permanent effects.

The risk of iatrogenic paresthesia of the third division of the trigeminal nerve depends on the procedure performed, the technique used and the surgeon’s experience. Iatrogenic paresthesia remains a complex clinical problem with major medicolegal implications. The purpose of this article is to present the authors’ clinical experience over the past 12 years, to review the principles of prevention and management of trigeminal paresthesia and to highlight the resulting medicolegal implications.

**Methods**

The files of all patients referred to the authors’ oral and maxillofacial surgery department between 1990 and 2001 for evaluation of iatrogenic paresthesia in the third division of the trigeminal nerve were reviewed. All patients had been seen and treated by the same surgeon. The data extracted from the files included age, sex, description of the trauma, lesion location, initial diagnosis, need for microsurgery and type of surgery performed. The sample was divided into 2 subgroups according to whether the patient had initiated a lawsuit against the dentist who had performed the surgery. These subgroups were compared by the Student t-test to determine whether any of the independent variables were associated with initiation of lawsuits.

**Results**

The cohort consisted of 165 patients. The most common cause of paresthesia in the third division of the trigeminal nerve was extraction of impacted third molars (109 patients), followed by trauma due to injection (19 patients) (Table 1). In 135 patients, the lesion was located at the level of a single nerve, the lower alveolar nerve in 82 (61%) of these patients and the lingual nerve in 53 (39%). Twenty-one patients had bilateral pain in the lower alveolar or the lingual nerve, and 9 patients had pain in both of these nerves on the same side. One hundred and fourteen (69%) of the subjects were female (ratio of women to men 2.2:1). During the initial evaluation, most patients presented with hypoesthesia (103 [62%]) or anesthesia (17 [10%]). Dysesthesia was seen in 36 (22%) of the cases, and the proportion of female subjects was significantly higher in this subgroup \( p = 0.007 \). Thirty-three patients (20%) underwent microsurgery for ablation of a neuroma, reanastomosis or neural decompression.

Legal proceedings were initiated by 33 (20%) of the 165 patients. Patients who initiated lawsuits were younger, were more likely to have experienced anesthesia and were more likely to have needed microsurgery (Table 2). The average amount granted in the legal proceedings was $17,956, which was 42% of the average amount requested, $43,047 (Table 3). The highest amount awarded was $35,347 and the lowest $5,167. Most disputes were settled amicably or out of court. In general, higher amounts were granted to patients who had recourse to a lawyer’s services.
Discussion

The reported incidence of paresthesia after extraction of impacted third molars varies between 0.2% and 22% for the lingual nerve and between 0.4% and 7% for the lower alveolar nerve. These variations can be explained by differences in procedures and technique, in particular with regard to clinical evaluation and diagnostic criteria, as well as differences in the surgeon's experience. The risk of paresthesia depends on the clinical situation. It may be almost nonexistent under the best conditions (young patient, incompletely formed roots, mandibular canal not in close proximity) but could exceed 50% in other circumstances (elderly patient, unfavourable position of the tooth, proximity of the mandibular canal). A good clinical evaluation can be used to inform the patient about the potential risks of surgery. Written informed consent, after the patient has received a complete description of these risks, must be obtained in all cases of nontherapeutic surgical removal of the molars (i.e., preventive treatment). Consent is also strongly recommended in cases of therapeutic surgical extraction (treatment of pathology) for semi-impacted or impacted third molars.

Among patients with iatrogenic paresthesia in the third division of the trigeminal nerve, 75% regain normal sensitivity without further treatment. In most cases, complete recovery occurs 6 to 8 weeks after the trauma, although it may take up to 24 months. If paresthesia is not completely resolved within about 2 months, the probability of a permanent deficit increases significantly; it is unlikely that complete resolution will occur if the deficit is still present after 9 months. The prognosis of spontaneous recovery is better for the lower alveolar nerve than for the lingual nerve.

In the preoperative evaluation for nontherapeutic extraction of impacted third molars, the surgeon must decide whether the risks of surgery exceed the expected benefits. This study and the authors' clinical experience have shown that, too often, the risk of surgery had been poorly evaluated and, in certain cases, the treatment is not even indicated. The surgeon must be familiar with the indications for removal of impacted third molars (Table 4). He or she must also be familiar with the radiologic signs indicating the proximity of the lower alveolar nerve. The presence of a radiolucent band at the apex of the third molar, loss of continuity of the upper or lower bony cortex in the lower alveolar canal and shrinking or deviation of this canal are all reliable signs indicating closer proximity of the lower alveolar nerve to the root of the wisdom tooth (Figs. 1 to 3).

Management

Perioperative Precautions

If the patient feels a sensation like an electric shock when the needle is inserted, the needle should be withdrawn by a few millimetres before the solution is administered. If the position of the extracted tooth allows the lower alveolar nerve to be seen at the bottom of the alveolus, many surgeons prefer to place a piece of absorbable gelatin in the alveolus (e.g., Gelfoam, Pharmacia & Upjohn Co, Kalamazoo, Mich.) before closing. However, the
effectiveness of this measure, which aims to minimize fibrosis and thus prevent paresthesia, has not been established.

**Clinical Evaluation**

Patients with postoperative paresthesia must be treated promptly and should be seen as soon as possible for clinical evaluation. The clinical evaluation should comprise the following elements:

1. Map the affected area by pencil outline on a drawing or a photograph of the patient (Fig. 4).
2. Determine the sensations felt by the patient when a cotton swab is lightly applied to the affected area (Fig. 5).
3. Determine the ability of the patient to detect the direction of a sweeping motion (in an area of about 1 cm), applied with a resin applicator or the tip of a rolled-up tissue (Fig. 6).
4. Describe the patient's sensations when a 27-gauge hard needle is applied in the affected region with sufficient pressure to indent the skin without penetrating it (Fig. 7).

The presence of dysesthesia or spontaneous pain must be noted. Each test must be conducted at 3 sites: the lower lip, the lip–chin fold and the chin. Any patient with paresthesia should receive corticosteroids to minimize the inflammatory response.\textsuperscript{12} Empiric treatment with prednisone (50 mg once daily) for 7 days is often used in the authors' oral surgery department. This medication must be started as soon as possible, ideally the day after surgery.
Seven-day antibiotic treatment with penicillin, the gold standard for patients without penicillin allergy, or clindamycin is commonly prescribed to prevent infection, which would slow the healing process and decrease the likelihood of full recovery of the nerve. Clinical evaluation should be repeated once a month to assess the presence or absence of functional recovery.

**Referring the Patient**

Some patients must be referred to an oral and maxillofacial surgeon. Microsurgery may be indicated in the following cases: confirmed transection of a nerve; total anesthesia of the affected area 2 months after the trauma; lack of protective reflexes (on biting or burning of the tongue or lower lip) 2 months after trauma, with little or no improvement; or dysesthesia.

Microsurgery involves general anesthesia, a period of convalescence and a few weeks off work. The surgeon dissects the affected nerve and, if the damage is extensive, joins the proximal and distal portions. This surgery should ideally be done within 4 months after the trauma to prevent atrophy of the distal part of the nerve. Therefore, if it is felt that the patient’s condition might be improved through surgery (on the basis of the criteria listed above), he or she should be referred immediately to allow the surgeon to make his or her own assessment and measure the lack of functional recovery over a period of 2 months before intervening. Although considerable functional improvement is seen in many patients after surgery, regaining normal sensation is not possible. Just under half of patients experience no improvement, and all patients who undergo surgery will have some permanent sensory deficit. In cases of dysesthesia, a more medical approach is required, since surgery is rarely useful in these cases, especially for patients with sympathetically mediated pain or central neuropathic pain.

**Conclusions**

Most cases of iatrogenic paresthesia can be prevented. However, when this problem occurs, follow-up must be initiated quickly, since the first few months may determine the degree of nerve healing. If there is a high risk of nerve trauma, the patient should be referred preoperatively to an oral and maxillofacial surgeon. Most patients recover normal sensation without treatment. However, permanent deficits are often poorly tolerated, as indicated by the high proportion of lawsuits in such cases. More than half of lawsuits are associated with lack of preoperative informed consent. In-depth knowledge of anatomy and surgical principles is also imperative. It is often easy to treat slight hypoesthesia, but treatment becomes complex in cases of sympathetically mediated pain or central neuropathic pain. If a large area has been affected, it is impossible to regain normal sensation regardless of the therapeutic measures undertaken. The well-informed general dentist should be able to perform an initial assessment and then refer the patient to a maxillofacial surgeon at the appropriate time to maximize the chances of functional recovery of the affected nerve.
